

Spin Tunneling in Fe_8 molecular nanomagnets[Comment on
Europhys. Lett. 47, 722 (1999) by DEL BARCO et al]

G. Bellessa

Chudnovsky and Tejada have published without asking for my agreement a paper in Europhysics Letters (Ref. [1]) on an experiment done in my research group in Orsay by Del Barco, Vernier and myself. The Fe_8 sample was furnished by Tejada.

I shall not comment on this behavior, but I want to notice two important points:

- The first one is about the way the experiment is presented in Ref. [1] as the observation of mesoscopic quantum coherence, when it is more simply an EPR experiment that allows to observe the transitions inside the fundamental doublet of the Fe_8 cluster splitted by the magnetic field perpendicular to the easy magnetic axis of this one, as described by Korenblit and Shender [2].

Figure 1: *Magnetization of the Fe_8 powder at 2 K for the magnetic field parallel to the orientation axis (the empty triangles) and perpendicular to the orientation axis (the empty circles).*

- The second point is about the assertion that “the orientation of the powder was done by solidifying an epoxy (Araldit) with Fe_8 micrometric crystallites buried inside, in a 5.5 T field at 290 K during 12 hours”. This assertion is suspicious because the interaction energy between magnetic ions inside the Fe_8 clusters is much smaller than the thermal energy at room temperature. Therefore, I have measured the magnetization of *the sample that was used in the experiment of Ref. [1]* with a SQUID magnetometer at 2 K. The results are reported in Fig. 1. It can be seen that there is no significant difference between the magnetization curve for the magnetic field parallel to the powder orientation

axis and the one for the magnetic field perpendicular to the powder orientation axis. It is the same in Fig. 1 of Ref. [1]. The main peaks for the two orientation axes appear different on the high-field side but they are similar on the low-field side. So, the difference between the two curves is rather due to a change in the base-line.

To conclude, the susceptibility peak reported in Ref. [1] is observed in a non-oriented powder. Only the crystallites that have their easy axis almost perpendicular to the magnetic field take part in the susceptibility peak. This explains why the signal corresponds to a quite small part of the magnetic moments in the sample.
